

What is the endocrine system?

The endocrine system is a network of glands that produce hormones. These hormones regulate the body's metabolism, growth and development, mood, and other functions. The endocrine system is also responsible for the body's response to stress and for the regulation of the immune system.

The endocrine system is made up of several glands, including the hypothalamus, pituitary, thyroid, parathyroid, adrenal, and gonads. The hypothalamus and pituitary glands are located in the brain, while the thyroid and parathyroid glands are located in the neck. The adrenal glands are located on top of the kidneys, and the gonads are the testes in males and the ovaries in females.

Thymus

The thymus is a small gland located in the upper chest area. It is responsible for the production and maturation of T-lymphocytes, which are a type of white blood cell that plays a key role in the body's immune system.

Heart

The heart is a muscular organ that pumps blood throughout the body. It is located in the chest area, between the lungs. The heart is made up of four chambers: the right and left atria and ventricles.

The endocrine system and hormones

The endocrine system is a network of glands that produce hormones. These hormones regulate the body's metabolism, growth and development, mood, and other functions. The endocrine system is also responsible for the body's response to stress and for the regulation of the immune system.

Feedback to the primary

Feedback to the primary endocrine gland is a process that helps to maintain the balance of hormones in the body. It involves the release of hormones by the target organs, which then travel back to the primary gland to inhibit its further release.

Action of hormones

Hormones can act in several ways. Some hormones act on the target cells by binding to receptors on the cell surface, while others act by entering the cell and binding to intracellular receptors. The action of hormones is often regulated by feedback loops.

Reproductive organs

The reproductive organs are responsible for the production and development of the offspring. In males, these include the testes and the prostate gland. In females, these include the ovaries, uterus, and vagina.

Medical

The endocrine system is a complex system that is essential for the body's health and well-being. Disorders of the endocrine system can lead to a wide range of symptoms, including changes in weight, mood, and energy levels.

Doctor 022

The hypothalamus and pituitary gland

The hypothalamus is a small region of the brain that plays a key role in the endocrine system. It is responsible for the production and release of hormones that regulate the body's metabolism, growth and development, mood, and other functions. The pituitary gland is a small, pea-sized gland located at the base of the brain. It is responsible for the production and release of hormones that regulate the body's metabolism, growth and development, mood, and other functions.

Digestive system

The digestive system is responsible for the breakdown of food into nutrients that can be used by the body. It consists of the mouth, esophagus, stomach, small intestine, and large intestine. The digestive system is also responsible for the absorption of nutrients and the elimination of waste.

Pancreas

The pancreas is a gland located in the abdominal cavity. It is responsible for the production and release of hormones that regulate the body's metabolism, growth and development, mood, and other functions. The pancreas is also responsible for the production and release of enzymes that are used in the digestion of food.

Function of insulin

Insulin is a hormone that is produced by the beta cells of the pancreas. It is responsible for the regulation of blood glucose levels. Insulin allows glucose to enter the cells, where it is used for energy. Without insulin, glucose cannot enter the cells, and blood glucose levels rise.

Reproductive organs

The reproductive organs are responsible for the production and development of the offspring. In males, these include the testes and the prostate gland. In females, these include the ovaries, uterus, and vagina.

Medical

The endocrine system is a complex system that is essential for the body's health and well-being. Disorders of the endocrine system can lead to a wide range of symptoms, including changes in weight, mood, and energy levels.

The first lecture in signal transduction

An overview of what we will learn during these lectures :

We will define different mechanisms for signaling transduction and this actually to understand the way of ligand to induce their effects in our body . The scope of these lectures is to understand the mechanism for ligand actions ,different types of ligand in terms of chemical structure . We will describe many receptor types and their interactions also we will know what we mean by second messengers that are used by different hormones in order to induce their effects .

Objectives:

- Define first messenger (Hormones)
- List hormone types
- Describe receptor types
- Outline the hormone receptors interactions
- Describe second messenger mechanism of action
- List second messengers

What will be explained in the signaling transduction lectures .

Signaling Overview

1. Introduction
 - A. Definitions
 - B. Components involved in signaling
 - C. Types of signaling
2. Types of Signaling Ligands - cell-surface vs. intracellular
3. Three Major Classes of Signaling Receptors
 - A. Ion Channel-linked
 - B. G protein-coupled receptors (GPRs)
 - C. Enzyme-linked receptors
 - A. Tyrosine-Kinase Receptors
 - B. Overview
 - C. Mechanism of activation
 - D. Different ways that TKRs can be activated
 - E. TKs that are non-covalently linked with receptors
4. Second Messengers: cAMP, cGMP, IP3 and DAG, Ca²⁺, PIP3
5. Signaling Cascades
 - A. Ras GTPase
 - B. Adaptor proteins with SH2 and SH3 domains
 - C. MAP kinase pathway
 - D. 5 different kinases activated by different cascades
 - E. JAK-STAT pathway

4

What we mean by signaling ?

Cell -cell communication via signals .

Signal transduction :

Process of converting extracellular signals into intra-cellular responses .

Ligand:

The signaling molecule .

Receptors :

Specific protein that bind specific ligand on its binding site in order to transmit signals to intracellular targets **Different receptors can respond differently to the same ligand .

If the ligand binds to more than one type of receptor ,we will find different actions ,because actions depends not only on the ligand but also in the receptor .

Component involved in signaling :

1-Ligands

2 -Receptores

3-intracellular signaling proteins

4-intermediary proteins

5-Enzymes

Which induce different metabolic activities in the cell

6-second messengers

7-target proteins

8-inactivating proteins

Overview of Signal Transduction

Figure 15-1. Molecular Biology of the Cell, 4th Edition.

Note that we have a set of protein involved in signaling transduction :

Starting from ligand (signal) , receptors that bind ligand and other intracellular signaling proteins involved .

Over view of signal transduction

We have ligand ,recptor , different signaling proteins (mediators to transmit signal) these mediators could be seond messenger and at the end we have target proteins .

Target protein could be an activity of an enzyme or it could be a gene regulatory protein (in order to change the expression of a certain gene) or it could be a cytoskeletal protein that will change the structure of the protein or maybe the movement and shape of the cell .

The main functions of signaling

Internal and external environment in the cell is always changing so the cell must respond to these changes in order to maintain homeostasis ,so cells try to adjust to their environment and that happens due to signaling between stimuli& between the cells [this is the way cells can detect and respond to their environmental changes ,such as in oxygen availability ,sugar availability or in temperature .

Sometimes the signal is not just switch on and off but also we have graded signals which may induce cells to differentiate into different types of cells ,there are so many different types of signaling that can take place *different intensities of certain signal can have different outcomes or different effects on cell and that what we may see in the differentiation of cells

يمكن شدة الاشارة
تأثير على نوع الخلية المتمايزة .

Combined actions of transcription factors create different cell types
Sometimes we have combined actions of different signals and factors can create different cell type (and that is also we see in differentiation) so we are not talking about one signal per cell,we are talking about a group combination of signals that have different actions and different effects on transcription factors *so different combination can create different type of cells and also important for cell differentiation

Lateral inhibition signals prevent duplication of unique cell types
Signals are not always excitatory ,it can be inhibitory for a certain cell maybe stop duplication or stop proliferation

Integration of signals allows cells to adjust to their neighbors and to change with time
Different signals integrate and then together can help the cell to adjust to some external changes to the external environment or to act differently or change with time

Signaling is responsible for how cells can respond to their environment and how they can differentiate or change over time .

***The main mechanism for cell signaling ***

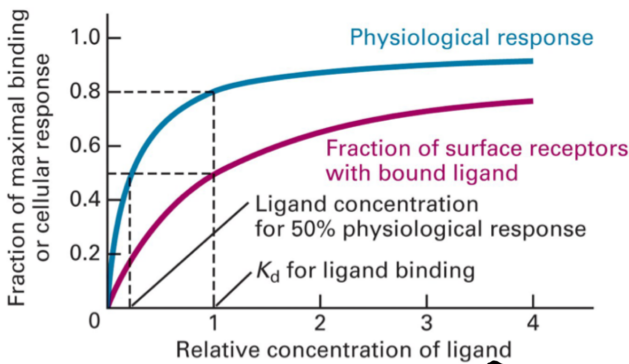

Ligand was secreted by maybe hormone secreting cells(gland) .This ligand will find a specific receptor for maybe on the neighboring cell and bind with this specific receptor . This receptor -ligand binding will induce changes in the receptor such as conformational change in the structure of the receptor which will induce other proteins that can bind to the receptor inside the cell .

So the binding of the ligand transduced changes at the intracellular level ,and these changes will be transduced into different target protein in the cell ,and these mediators we can call it second messenger .

Second messenger transduce these changes into a cellular response ,increasing activity of a certain enzyme or substance -producing a certain product,it could directly go to the nucleus to induce changes in the gene expression and in production of receptors or enzymes or different proteins (structural proteins) .

As you can see here signals that are outside the cell are translated into cellular response ,and without having even to transport this signaling molecule into the cell that is what we call is **Transduction**

We don't necessarily need to transport the molecule itself into the cell to induce its actions ,only binding to the receptor can induce these actions .

The question now is,do we need all receptors to be bound to their ligand in order to have a certain physiological response ?

Look at this graph
On x-axis we have the relative concentration of a ligand which is normal values of concentration .And on y-axis the fraction of maximal binding or cellular response .
The first curve which demonstrate the physiological response it could be like a contraction of a muscle .
The second curve which demonstrates the fraction of surface receptors that are bound with their ligand

محتويات الشكل :

Not all of the receptor needs to be bound to induce a response

We will explain why [Not all of the receptor need to be bound to induce a response] .

Let's see how the fraction of surface receptors bound to the ligand relative to the physiological response . Take the first concentration which is a normal concentration of a ligand .You can see even with 50%of a receptors bound to their ligand we can have ,close to maximal physiological response which is 0.8 or 80% .However we have 50% of the receptors occupied or bound to the receptor .

When we look at the double concentration of the ligand ,it induces more binding,so we will get about 70% or 65% of the receptors that bound to their ligand ,the physiological response is about 90%.

Notice that

At low concentration of ligand ,we achieve a response close to the maximal physiological response .And even when we doubled the concentration ,we did not get much increase in maximal physiological response (increasing in less than 10%) .We don't need to have all receptors bound to their ligands in order to induce a good response .

* Another characteristic of signals that signals can act locally or at a long distance from the secreting cell.

Another example of an signal ,sometimes signals are secreted by secreting cell or gland and then are transported via blood or through the circulation into a distant target cell .

Example : a hormone was secreted by pituitary gland(in the brain) and this signal (hormone) has to be transported or carried by the blood to go to a distant target such as ,muscle cell or bone cell in lower limb muscles and must know that endocrine hormones use this way for signaling via blood without ducts.That's why it called the endocrine (having no duct) .

on the right ,we have this example of signal secreted by a cell and the target is binding to the neighboring cell's receptors ,so the signal acted locally through a short distance from the secreting cells and then bound to receptors on the target cell which is very close to the secreting cells In this case we call this signals **local mediators**.

5 Types of signaling

(A) CONTACT-DEPENDENT

The two neighboring cells are in direct contact via binding of plasma protein .

(B) PARACRINE

The cell secretes a signal that travel short distance ,binding on neighboring cell's receptors and signals that use this type of signaling known as local mediators or local factors .

(C) SYNAPTIC

It's nearly similar to paracrine but the main difference in this type that we have a synapse between cells and the type of cells is neurons ,so the neurotransmitters (signal) cross the axon and bind to the other neuron of ligand target channel via synapse

(D) ENDOCRINE

Signals here called hormone and this hormone which is secreted from endocrine cell or gland can transport to a distant target cell via blood stream e.g: pituitary gland as we mentioned before

And the last type of signaling is autocrine , when a secreted signal binds to the receptors on the same secreting cells.meaning that I have the signal and receptor on the same cell.Usually this type of signal is considered as a feedback of the cell .how ? When cell secretes a signal ,this signal maybe bind on the receptors on the same cell (which secreted a signal)to inhibit the cell (negative feedback) .

Types of signaling ligands

A. Ligands that bind to cell-surface receptors:

- ① Neurotransmitters (NT), i.e. norepinephrine, histamine - hydrophilic (charged, polar)
- ② Peptide hormones (P), i.e. insulin - can't cross membrane
- ③ Growth factors (GF), i.e. NGF, EGF, PDGF
- ④ Lipophilic signaling molecules, i.e. prostaglandins

The cell surface receptors are integral proteins cross the cell membrane through extracellular domain ,and this extacellular domain has a specific binding site , these ligands has a characteristic that they charged polar (they cannot cross the plasma membrane) or peptides (large also cannot cross) So usually these ligand cannot cross the membrane (even some lipophilic signaling molecule has charge so they can't cross the membrane without receptors)

B. Ligands that bind to intracellular receptors:

lipid soluble hormones that diffuse across the plasma membrane and interact with receptors in the cytosol or nucleus. i.e. steroids, thyroxine, retinoic acid, nitric oxide.

They can freely cross the plasma membrane by simple diffusion and then interact with intracellular receptors on the cytosol or sometimes even to the nucleus

Local vs. Circulating hormones

18.02
Pablo 552, J. R. Lingappa

As we discussed previously there are two types of hormones :

1-Hormones that affect locally which we call it paracrine or autocrine ,so their target cells are present locally very close to the secreting cells or (same cell will be affected in autocrine) .

2-circulating hormones “Endocrine hormones “when the signaling molecules travel via the blood circulation and then affect the distant target cell .

Let's look at the chemical classifications of hormones .Hormones are divided into either lipid soluble or lipid insoluble hormones .

****For the lipid soluble hormones** Use transport proteins in the plasma

They can easily diffuse across the plasma membrane such as steroids .However in the plasma when they are transported,they have to use transporting proteins because they are lipophilic they don't like the media of plasma which is water mainly .When they reach their target ,they can diffuse across the plasma membrane .

Examples :

- 1- steroid
- A-testosterone.
- B-estradiol
- C-cortisol
- d-progesterone

Lipids derived from cholesterol and all types of steroids are lipophilic hormones

- 2-Thyroid (amine but lipid soluble) .
- 3-Nitric oxide(NO)is a gas and also highly permeable

**The water soluble hormones or in other terms the lipid insoluble hormones

These actually circulate freely in the plasma ,they are free form in the plasma (free from transport proteins) .

Examples :

1- Amines

hormones derived from tyrosine &tryptophan .

2-polypeptides

Chains of <100 amino acids in length such as ADH(antidiuretic hormone)

3-protein hormones

Polypeptide chains with >100 amino acids like growth hormone

4-Eicosanoid (Prostaglandins)derived from arachidonic acid(20carbon 4double bonds) .

They are Lipophilic,usually they found charged at a physiological PH (considered water soluble) so they cannot cross plasma membrane by simple diffusion .

Chemical Classification of Hormones

• Glycoproteins:

→ Long polypeptides (>100) bound to 1 or more carbohydrate (CHO) groups.

Examples : FSH and LH, TSH and hCG (human chorionic gonadotropin)

→ They have α and β subunits (α is common and β is specific)

*All of the lipophilic or hydrophilic hormones are glycoproteins

FSH~follicle stimulating hormone
LH~luteinizing hormone
TSH~thyroid stimulating hormone

• Hormones can also be divided into:

• Polar:

- H₂O soluble. Hydrophilic

• Nonpolar (lipophilic):

- H₂O insoluble.

- Can gain entry into target cells.

- Steroid hormones and T₄ (thyroxine –tetraiodothyronine))
